Abstract

Evolutionary dynamics combines game theory and nonlinear dynamics to model competition in biological and social situations. The replicator equation is a standard paradigm in evolutionary dynamics [1],

\[ \dot{x}_i = x_i(f_i(x) - \phi), \quad i = 1, \ldots, n \]  

(1)

where \( x_i \) is the frequency of strategy \( i \), \( f_i \) is its fitness, and \( \phi = \sum x_i f_i \) is the average fitness. In words, equation (1) says that the growth rate of each strategy’s frequency is its excess fitness, i.e. the deviation of its fitness from the average. The game-theoretic aspect of the model lies in the choice of fitness function, which is determined by a payoff matrix \( A \):

\[ f_i = (Ax)_i. \]  

(2)

Previous work by Ruelas and Rand [2] investigated the Rock-Paper-Scissors replicator dynamics problem with periodic forcing of the payoff coefficients. This work extends the previous to consider the case of quasiperiodic forcing. That is, the payoff matrix is

\[ A = \begin{pmatrix} 0 & -1 - F(t) & 1 + F(t) \\ 1 & 0 & -1 \\ -1 & 1 & 0 \end{pmatrix} \]  

(3)

where the forcing function \( F \) is given by

\[ F(t) = \varepsilon ((1 - \delta) \cos \omega_1 t + \delta \cos \omega_2 t). \]  

(4)

This model may find applications in biological or social systems where competition is affected by cyclical processes on different scales, such as days/years or weeks/years.

The methods used in this paper to study the quasiperiodically forced Rock-Paper-Scissors system (1)-(4) include (i) numerical simulation, (ii) computation of Lyapunov exponents, and (iii) harmonic balance to approximate the periodic solutions predicted by Floquet theory. We investigate the linear stability of the interior equilibrium point, where all three strategies coexist. We find that stability depends sensitively on the frequencies \( \omega_1 \) and \( \omega_2 \), and that the region of instability in the \( \omega_1 - \omega_2 \) plane exhibits self-similarity. As predicted by perturbation analysis [3], there are tongues of instability along the lines

\[ n\omega_1 + m\omega_2 = 2/\sqrt{3} \]  

(5)

for all pairs of integers \( (n,m) \).

It is shown that the results of the three methods are mutually consistent.
Figure 1: (Top) Transition curves in the $\omega_1 - \omega_2$ plane predicted by harmonic balance. (Bottom left) Region of instability given by numerical integration. (Bottom right) Contour plot of Lyapunov exponents. For all plots, $\varepsilon = 1.3, \delta = 0.6$.

Abstract

Evolutionary dynamics combines game theory and nonlinear dynamics to model competition in biological and social situations. The replicator equation is a standard paradigm in evolutionary dynamics. The growth rate of each strategy is its excess fitness: the deviation of its fitness from the average. The game-theoretic aspect of the model lies in the choice of fitness function, which is determined by a payoff matrix.

Previous work by Ruelas and Rand investigated the Rock-Paper-Scissors replicator dynamics problem with periodic forcing of the payoff coefficients. This work extends the previous to consider the case of quasiperiodic forcing. This model may find applications in biological or social systems where competition is affected by cyclical processes on different scales, such as days/years or weeks/years.

We study the quasiperiodically forced Rock-Paper-Scissors problem using numerical simulation, and Floquet theory and harmonic balance. We investigate the linear stability of the interior equilibrium point; we find that the region of stability in frequency space has fractal boundary.

1. Introduction

The field of evolutionary dynamics combines game theory and nonlinear dynamics to model population shifts due to competition in biological and social situations. One standard paradigm\textsuperscript{9,3} uses the replicator equation,

\[
\dot{x}_i = x_i(f_i(x) - \phi), \quad i = 1, \ldots, n
\]  

(1)

where \(x_i\) is the frequency, or relative abundance, of strategy \(i\); the unit vector \(x\) is the vector of frequencies; \(f_i(x)\) is the fitness of strategy \(i\); and \(\phi\) is the average fitness, defined by

\[
\phi = \sum_i x_i f_i(x).
\]  

(2)
The game-theoretic component of the replicator model lies in the choice of fitness functions. Define the payoff matrix \( A = (a_{ij}) \) where \( a_{ij} \) is the expected reward for a strategy \( i \) individual vs. a strategy \( j \) individual. We assume the population is well-mixed, so that any individual competes against each strategy at a rate proportional to that strategy’s frequency in the population. Then the fitness \( f_i \) is the total expected payoff for strategy \( i \) vs. all strategies:

\[
f_i(x) = (Ax)_i = \sum_j a_{ij}x_j, \tag{3}
\]

In this work\(^{10} \), we generalize the replicator model to systems in which the payoff coefficients are quasiperiodic functions of time. Previous work by Ruelas and Rand\(^7,8 \) investigated the Rock-Paper-Scissors replicator dynamics problem with periodic forcing of the payoff coefficients. We also consider a forced Rock-Paper-Scissors system. The quasiperiodically forced replicator model may find applications in biological or social systems where competition is affected by cyclical processes on different scales, such as days/years or weeks/years.

2. The model

2.1. Rock-Paper-Scissors games with quasiperiodic forcing

Rock-Paper-Scissors (RPS) games are a class of three-strategy evolutionary games in which each strategy is neutral vs. itself, and has a positive expected payoff vs. one of the other strategies and a negative expected payoff vs. the remaining strategy. The payoff matrix is thus

\[
A = \begin{pmatrix}
0 & -b_2 & a_1 \\
a_2 & 0 & -b_3 \\
-b_1 & a_3 & 0
\end{pmatrix}.
\tag{4}
\]

The case \( a_1 = \cdots = b_3 = 1 \) describes the Rock-Paper-Scissors game as played in real life, and thus can be considered the canonical RPS payoff matrix. We perturb off of this case by taking

\[
A = \begin{pmatrix}
0 & -1 - F(t) & 1 + F(t) \\
1 & 0 & -1 \\
-1 & 1 & 0
\end{pmatrix},
\tag{5}
\]

where the forcing function \( F \) is given by

\[
F(t) = e((1 - \delta) \cos \omega_1 t + \delta \cos \omega_2 t).
\tag{6}
\]

For ease of notation, write \((x_1, x_2, x_3) = (x, y, z)\). The dynamics occur in the 3-simplex \( S \), but since \( x, y, z \) are the frequencies of the three strategies, and hence \( x + y + z = 1 \), we can eliminate \( z \) using \( z = 1 - x - y \). Therefore, the region of interest is \( T \), the projection of \( S \) into the \( x-y \) plane:

\[
T = \{(x, y) \in \mathbb{R} | (x, y, 1 - x - y) \in S \}.
\tag{7}
\]

Thus the replicator equation (1) becomes

\[
\dot{x} = -x(x + 2y - 1)(1 + (x - 1)F(t)) \tag{8}
\]

\[
\dot{y} = y(2x + y - 1 - x(x + 2y - 1)F(t)) \tag{9}
\]

Note that \( \dot{x} = 0 \) when \( x = 0 \), \( \dot{y} = 0 \) when \( y = 0 \), and

\[
\dot{x} + \dot{y} = (x + y - 1)(xF(t)(x + 2y - 1) - x + y)
\tag{10}
\]

so that \( \dot{x} + \dot{y} = 0 \) when \( x + y = 1 \), which means that \( x + y = 1 \) is an invariant manifold. This shows that the boundary of \( T \) is invariant, so trajectories cannot escape the region of interest.

It is known\(^4 \) that in the unperturbed case \((\epsilon = 0)\) there is an equilibrium point at \((x, y) = (\frac{1}{4}, \frac{1}{4})\), and the interior of \( T \) is filled with periodic orbits. We see from equations (8)-(9) that this interior equilibrium point persists when \( \epsilon \neq 0 \). Numerical integration suggests that the Lyapunov stability of motions around the equilibrium point depends sensitively on the values of \( \omega_1 \) and \( \omega_2 \). See Figure 1. We investigate the stability of the interior equilibrium using Floquet theory and harmonic balance, as well as by numerical methods.
2.2. Linearization

To study the linear stability of the equilibrium point, we set \( x = u + \frac{1}{3}, y = v + \frac{1}{3} \), substitute these into (8)-(9) and linearize, to obtain

\[
\dot{u} = -\frac{1}{9}(u + 2v)(3 + 2F(t))
\]
\[
\dot{v} = \frac{1}{9}(F(t)(u + 2v) + 3(2u + v)).
\]

The linearized system (11)-(12) can also be written as a single second-order equation on \( u \), by differentiating (11) and substituting in expressions for \( \dot{v} \) from (12) and \( v \) from (11). This gives us

\[
g(t)\ddot{u} - \dot{g}(t)\dot{u} - \frac{1}{9}g^2(t)u = 0
\]

where

\[
g(t) = -3 - 2F(t) = -3 - 2\epsilon((1 - \delta) \cos \omega_1 t + \delta \cos \omega_2 t).
\]

Now that we have a linear system with coefficients that are functions of time, we use Floquet theory to determine the stability of the origin.

3. Floquet theory

Floquet theory is concerned with systems of differential equations of the form

\[
\frac{dx}{dt} = M(t)x, \quad M(t + T) = M(t).
\]

We have the system (11)-(12), which can be written as

\[
\begin{bmatrix}
\dot{u} \\
\dot{v}
\end{bmatrix} = \frac{1}{9} \begin{bmatrix}
g(t) & 2g(t) \\
\frac{1}{2}(9 - g(t)) & -g(t)
\end{bmatrix} \begin{bmatrix}
u \\
v
\end{bmatrix}
\equiv B(t) \begin{bmatrix}
u \\
v
\end{bmatrix}
\]

where \( g(t) \) is as in (14).
In general, $B(t)$ is not periodic, since $\omega_1$ and $\omega_2$ are rationally independent. However, the set of points for which $\omega_1$ and $\omega_2$ are rationally dependent is dense in the $\omega_1 - \omega_2$ plane, and solutions of (16) must vary continuously with $\omega_1$ and $\omega_2$, so it is reasonable to consider only the case that $F(t)$, and hence $g(t)$ and $B(t)$, are in fact periodic.

Assume that $\omega_2 = \frac{a}{b}\omega_1$ in lowest terms, where $a$ and $b$ are relatively prime integers. Then we can make the change of variables $\tau = \omega_1 t$, so $\omega_2 t = \frac{a}{b} \tau$. Since $a$ and $b$ are relatively prime, we see that $F$, and hence $g$ and $B$, have period $T = 2\pi b$ in $\tau$. Thus (16) becomes

$$\begin{bmatrix} u' \\ v' \end{bmatrix} = \frac{1}{\omega_1} B(\tau) \begin{bmatrix} u \\ v \end{bmatrix}, \quad B(\tau + 2\pi b) = B(\tau)$$

(17)

where $u'$ indicates $du/d\tau$. This has the same form as (15), so we can apply the results of Floquet theory.

Suppose that there is a fundamental solution matrix of (17),

$$X(\tau) = \begin{bmatrix} u_1(\tau) & u_2(\tau) \\ v_1(\tau) & v_2(\tau) \end{bmatrix}, \quad X(0) = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}.$$  

(18)

Then the Floquet matrix is $C = X(T) = X(2\pi b)$, and stability is determined by the eigenvalues of $C$:

$$\lambda^2 - (\text{tr} C)\lambda + \det C = 0.$$  

(19)

We can show that $\det C = 1$, as follows. Define the Wronskian

$$W(\tau) = \det X(\tau) = u_1(\tau)v_2(\tau) - u_2(\tau)v_1(\tau).$$  

(20)

Notice that $W(0) = \det X(0) = 1$. Then taking the time derivative of $W$ and using (17) gives

$$\frac{dW}{d\tau} = \frac{1}{\omega_1} W(\tau) \text{ tr } B(\tau) = 0.$$  

(21)

This shows that $W(\tau) = 1$ for all $\tau$, and in particular $W(T) = \det C = 1$. Therefore,

$$\lambda = \frac{\text{tr} C \pm \sqrt{\text{tr} C^2 - 4}}{2}$$  

(22)

which means that the transition between stable and unstable solutions occurs when $|\text{tr} C| > 2$, and this corresponds to periodic solutions of period $T = 2\pi b$ or $2T = 4\pi b$.

Given the period of the solutions on the transition curves in the $\omega_1 - \omega_2$ plane, we use harmonic balance to approximate those transition curves.

4. Harmonic balance

We seek solutions to (13) of period $4\pi b$ in $\tau$:

$$u = \sum_{k=0}^{\infty} \alpha_k \cos \left( \frac{kt}{2b} \right) + \beta_k \sin \left( \frac{kt}{2b} \right).$$  

(23)

Since $\omega_2 = \frac{a}{b}\omega_1$ where $a$ and $b$ are relatively prime, any integer $k$ can be written as $na + mb$ for some integers $n$ and $m$. That is, there is a one-to-one correspondence between integers $k$ and ordered pairs $(m, n)$. We can therefore write the solution as

$$u = \sum_{m=0}^{\infty} \sum_{n=\infty}^{\infty} \alpha_{mn} \cos \left( \frac{ma + nb}{2b} \tau \right) + \beta_{mn} \sin \left( \frac{ma + nb}{2b} \tau \right) + \sum_{m=0}^{\infty} \sum_{n=-\infty}^{\infty} \alpha_{mn} \cos \left( \frac{m\omega_2 + n\omega_1}{2} \tau \right) + \beta_{mn} \sin \left( \frac{m\omega_2 + n\omega_1}{2} \tau \right).$$  

(24)

(25)
We substitute a truncated version of (25) into (13), expand the trigonometric functions and collect like terms. This results in cosine terms whose coefficients are functions of the \(a_{mn}\), and sine terms whose coefficients are functions of the \(\beta_{mn}\). Let the coefficient matrices of these two sets of terms be \(Q\) and \(R\), respectively. In order for a nontrivial solution to exist, the determinants of both coefficient matrices must vanish\(^5\). We solve the equations \(\det Q = 0\) and \(\det R = 0\) for relations between \(\omega_1\) and \(\omega_2\). This gives the approximate transition curves seen in Figure 2.

It has been shown\(^7\) that in a periodically forced RPS system (i.e. \(\delta = 0\) in our model) there are tongues of instability emerging from \(\omega_1 = 2/n \sqrt{3}\) in the \(\omega_1 - \epsilon\) plane. Our harmonic balance analysis is consistent with this: we observe bands of instability around \(\omega_1 = 2/\sqrt{3}\) and \(\omega_2 = 2/\sqrt{3}\), which get broader as \(\epsilon\) increases. We also see narrower regions of instability along the lines \(n\omega_1 + m\omega_2 = 2/\sqrt{3}\), for each \(n, m\) used in the truncated solution (25).

Thus the boundary of the region of instability exhibits self-similarity when we consider \(\omega_1, \omega_2 \in [0, 2^{1-k}]\) for \(k = 0, 1, \ldots\).

5. Numerical integration

In order to check the results of the harmonic balance method, we generate an approximate stability diagram by numerical integration of the linearized system (13).

For randomly chosen parameters \((\omega_1, \omega_2) \in [0, 2]\), we choose random initial conditions \((u(0), u(t(0)))\) on the unit circle - since the system is linear, the amplitude of the initial condition needs only to be consistent between trials. We then integrate the system for 1000 time steps using ode45 in Matlab. We considered a motion to be unstable if \(\max |u(t)| > 10\). The set of points \((\omega_1, \omega_2)\) corresponding to unstable motions were plotted using matplotlib.pyplot.pieplot in Python. See Figure 3. Each plot in Figure 3 contains approximately \(5 \times 10^{5}\) points.

We note that the unstable regions given by numerical integration appear to be consistent with the transition curves predicted by harmonic balance (Figure 2). The regions of instability around \(\omega_1 = 2/\sqrt{3}\) and \(\omega_2 = 2/\sqrt{3}\) are visible for all tested values of \(\epsilon\) and \(\delta\), and as \(\epsilon\) increases, more tongues of the form \(n\omega_1 + m\omega_2 = 2/\sqrt{3}\) become visible.

6. Lyapunov exponents

A second, and more informative, numerical approach for determining stability is the computation of approximate Lyapunov exponents. This is a measure of a solution’s rate of divergence from the equilibrium point\(^1\), and is defined as

\[
\lambda = \lim_{t \to \infty} \sup_{\substack{t \to \infty}} \frac{1}{t} \ln |u(t)|. \tag{26}
\]

A positive Lyapunov exponent indicates that the solution is unstable.

We do not find any negative Lyapunov exponents, but note\(^5\) that the system (13) can be converted to a Hill’s equation

\[
\ddot{z} - \dot{z} \left( \frac{4g(t)^3 + 27g(t)^2 - 18g(t)\dot{g}(t)}{36g(t)^2} \right) = 0 \tag{27}
\]

by making the change of variables \(u = \sqrt{\dot{g}(t)}z\). Since \(\sqrt{\dot{g}(t)}\) is bounded, \(u\) is bounded if and only if \(z\) is bounded. And since there is no dissipation in (27), stable solutions correspond to \(\lambda = 0\).

We approximate the Lyapunov exponents numerically by integrating as above, and taking

\[
\lambda \approx \sup_{\substack{900 < t < 1000}} \frac{1}{t} \ln |u(t)|. \tag{28}
\]

See Figure 4. The shape of the unstable region is the same as in Figure 3, but this method allows us to see a sharp increase in unstable solutions’ rate of growth along the line \(\omega_1 = \omega_2\).

7. Conclusion

The replicator equation with quasiperiodic perturbation may be used to model biological or social systems where competition is affected by cyclical processes on different scales. We have investigated the linear stability of the interior
equilibrium point for RPS systems with quasiperiodic perturbation, using Floquet theory and harmonic balance, as well as numerical integration and numerical computation of Lyapunov exponents. We find that stability depends sensitively on the frequencies $\omega_1$ and $\omega_2$, and that the region of instability in the $\omega_1 - \omega_2$ plane exhibits self-similarity.
